ABSTRACT
This paper addresses the problem of distributed estimation of a parameter vector in the presence of noisy input and output data as well as data faults, performed by a wireless sensor network in which only local interactions among the nodes are allowed. In the presence of unreliable observations, standard estimators become biased and perform poorly in low signal-to-noise ratios. We propose two different distributed approaches based on the Expectation-Maximization algorithm: in the first one the regressors are estimated at each iteration, whereas the second one does not require explicit regressor estimation. Numerical results show that the proposed methods approach the performance of a clairvoyant scheme with knowledge of the random data faults.

Index Terms—Diffusion, distributed estimation, expectation-maximization, sensor networks, total least squares.

1. INTRODUCTION
We study the problem of distributed estimation of an unknown parameter vector when both the observations (output data) and the regressors (input data) are assumed noisy. The estimation is performed by a wireless sensor network (WSN) where the nodes are allowed to communicate within a small neighborhood only, and where some nodes may be subject to random transducer faults, in which case, the sensor is assumed to observe only noise [1, 2]. When dealing with noisy input and output data, a good alternative is the Total Least Squares (TLS) solution [3, 4], for which distributed implementations have been reported in the literature [5–7]. However, in the presence of data faults in the output data, the standard TLS estimation becomes biased, with the consequent penalty in the Mean Square Error (MSE). Treating the random data faults as hidden random variables, we derive two distributed estimators based on the Expectation-Maximization (EM) algorithm, a numerical method to compute the maximum-likelihood (ML) estimator in the presence of incomplete observations [9, 10]. As in previous contributions, the information is spread across the network by means of diffusion strategies [11], where a slower term for information diffusion is combined with a faster term for information averaging [7, 8]. The estimation is performed based on a single data snapshot collected by each node, i.e., there is no new data streaming in. The two implementations proposed differ in that, in the first one, the regressors are estimated at each iteration of the EM algorithm, whereas in the second they are not.

2. PROBLEM STATEMENT
Consider the problem of estimating a parameter vector \( \mathbf{x} \in \mathbb{R}^L \) based on a set of noisy observations

\[
\begin{align*}
\mathbf{y}_i & = a_i \mathbf{h}_i^T \mathbf{x} + w_i, \quad (1) \\
\mathbf{z}_i & = \mathbf{h}_i + v_i \\
\end{align*}
\]

where \( w_i \sim \mathcal{N}(0, \sigma^2) \) and \( v_i \sim \mathcal{N}(0, r^2 \sigma^2 \mathbf{I}_L) \) for all \( i = 1, \ldots, N \). The random variables \( \{a_i\} \) are i.i.d. Bernoulli distributed with \( \text{Pr}(a_i = 1) = p \), and reflect whether a sensor has been subjected to a data fault: \( a_i = 1 \) shows that the \( i \)-th sensor correctly acquired the corresponding observation, whereas \( a_i = 0 \) shows that only noise was sensed. We assume that \( \{a_i, w_j, v_k\} \) are statistically independent for all \( \{i, j, k\} \). Note that in case of a data fault at the \( i \)-th sensor, only (1) is affected, but not (2). The regressors \( \mathbf{h}_i \) are only observed through the noisy estimates \( \mathbf{z}_i \), and the ratio \( r^2 \) of the regressor noise variance to the output noise variance is assumed known\(^1\). Whereas \( \mathbf{x} \) is the parameter of interest, \( p, \sigma^2 \) and \( \{\mathbf{h}_i\} \) are regarded as deterministic, unknown nuisance parameters. Let us define \( \mathbf{y} \doteq [y_1 \cdots y_N]^T \), \( \mathbf{H} \doteq [\mathbf{h}_1^T ; \cdots ; \mathbf{h}_N^T] \), \( \mathbf{Z} \doteq [\mathbf{z}_1^T \cdots \mathbf{z}_N^T] \) and \( \mathbf{A} \doteq \text{diag}(\alpha) \) with \( \alpha \doteq [a_1 \cdots a_N]^T \). When knowledge of \( \mathbf{A} \) is available, the clairvoyant Ordinary Least Squares (CV-OLS) estimator can be computed as

\[
\hat{\mathbf{x}}_{\text{CV-OLS}} = \arg \min_{\mathbf{x}} \left\| \mathbf{y} - \mathbf{A} \mathbf{x} \right\|^2 = (\mathbf{Z}^T \mathbf{A} \mathbf{Z})^{-1} \mathbf{Z}^T \mathbf{A} \mathbf{y}. \quad (3)
\]

This is the ML estimator of \( \mathbf{x} \) when \( r^2 = 0 \). However, this estimator is biased if the input data is noisy (\( r^2 > 0 \)). For known \( \mathbf{A} \), the ML estimators of \( \mathbf{x} \) and \( \{\mathbf{h}_i\} \) in (1)-(2) are the solutions to

\[
\min_{\mathbf{x}, \mathbf{H}} r^2 \left\| \mathbf{y} - \mathbf{A} \mathbf{H} \mathbf{x} \right\|^2 + \| \mathbf{Z} - \mathbf{H} \|^2_F. \quad (4)
\]

\(^1\)Introducing different unknown variances would result in an overparameterized problem, yielding lack of identifiability.
where $\| \cdot \|_F$ denotes the Frobenius norm. Problem (4) is a generalized TLS problem [4], and its solution (clairvoyant TLS) is given by
\[
\begin{bmatrix}
\hat{x}_{\text{TLS}} \\
1/r_{\text{TLS}}^2
\end{bmatrix} = \text{eigenvector of } \begin{bmatrix}
Z^T \\
yy^T
\end{bmatrix} A \begin{bmatrix}
Z \\
yy
\end{bmatrix}.
\tag{5}
\]
If one assumes $A = I$ in (4), the standard TLS solution $\hat{x}_{\text{TLS}}$ is obtained. However, $\hat{x}_{\text{TLS}}$ becomes biased when data faults are present. Therefore, in the sequel we discuss a means to rectify the evidence of the data, the likelihood function of the TLS solution $\hat{x}_{\text{TLS}}$ and $\hat{H}$.

3. ML ESTIMATION VIA THE EM ALGORITHM

Let $\theta = [x^T \ h_1^T \cdots h_N^T \ \sigma^2 \ \rho]^T$. Due to the independence of the data, the likelihood function of $\theta$ is given by
\[
f(y, Z | \theta) = \prod_{i=1}^N f(y_i | \theta) \cdot \prod_{j=1}^N f(z_j | \theta)
\tag{6}
\]
where
\[
f(y_i | \theta) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(y_i - \hat{h}_i^T x_i)^2}{2\sigma^2}} + (1 - p) e^{-\frac{y_i^2}{2\sigma^2}}
\tag{7a}
\]
and
\[
f(z_j | \theta) = \frac{1}{(2\pi\sigma^2)^{\frac{N}{2}}} e^{-\frac{|z_j - \hat{a}_i|^2}{2\sigma^2}}
\tag{7b}
\]
Maximizing (6) w.r.t. $\theta$ in closed form is not possible, and one has to resort to numerical methods. The EM algorithm is particularly well suited to problems like the one at hand in which hidden random variables (the $\{a_i\}$ in this case) are present. We denote $\{y, Z\}$ as the incomplete data set and $\{y, Z, a\}$ as the complete data set. Assume for the moment a centralized approach in which a single node has access to the set $\{y, Z\}$. Then, at iteration $t$ of the EM algorithm one performs the following:

1. $E$-step: given an estimate $\hat{\theta}_t$ and a trial value $\tilde{\theta}$ of $\theta$, compute the conditional expectation
\[
Q(\theta ; \tilde{\theta}_t) = E_{\tilde{\theta}} \left\{ \log f(y, Z, a | \tilde{\theta}) \right\}.
\tag{8}
\]

2. $M$-step: obtain the estimate for the next iteration as
\[
\tilde{\theta}_{t+1} = \arg \max_{\theta} Q(\theta ; \tilde{\theta}_t).
\tag{9}
\]

Since $Z$ and $a$ are statistically independent we have
\[
f(y, Z, a | \tilde{\theta}) = f(y | \tilde{\theta}, a) \cdot f(Z | \tilde{\theta}) \cdot f(a | \tilde{\theta}).
\tag{10}
\]
After some algebra we get
\[
f(y, Z, a | \tilde{\theta}) = \frac{1}{(2\pi\sigma^2)^{\frac{N}{2}}} e^{-\frac{|y - \hat{H} x|^2}{2\sigma^2}} \cdot \prod_{i=1}^N \tilde{a}_i (1 - \tilde{p})^{1-\tilde{a}_i},
\tag{11}
\]
and taking the logarithm yields
\[
\log f(y, Z, a | \tilde{\theta}) \propto -\frac{N(L + 1)}{2} \log \sigma^2 - \frac{1}{2r^2\sigma^2} \|Z - \hat{H}\|_F^2 - \frac{1}{2\sigma^2} \left( \|y - A\hat{H} x\|^2 \right) + \sum_{i=1}^N \tilde{a}_i \log \tilde{p} + (1 - \tilde{a}_i) \log (1 - \tilde{p}).
\]
Further, let $\hat{a}_{i,t} = \mathbb{E}_a (a_i | \tilde{\theta}_t, y, Z)$ and $\tilde{A}_t = \text{diag}(\hat{a}_{i,t})$ with $\hat{a}_{i,t} = [\hat{a}_1 \cdots \hat{a}_N]^T$. Then, $Q(\theta ; \tilde{\theta}_t)$ can be expressed as
\[
Q(\theta ; \tilde{\theta}_t) \propto -\frac{N(L + 1)}{2} \log \sigma^2 - \frac{1}{2r^2\sigma^2} \left( \|Z - \hat{H}\|_F^2 \right) + \sum_{i=1}^N \tilde{a}_i (1 - \hat{p}_i) \log (1 - \hat{p}_i).
\tag{12}
\]
where $\hat{S}_t = \sum_{i=1}^N \hat{a}_{i,t} |x_i|$. Note that, since $a_i$ is Bernoulli, one has $\hat{a}_{i,t} = \Pr(a_i = 1 | \tilde{\theta}_t, y, Z)$. Making use of Bayes’ theorem, these a posteriori probabilities can be obtained as follows
\[
\hat{a}_{i,t} = \frac{\hat{p}_i \rho_{i,t}^0 + (1 - \hat{p}_i) \rho_{i,t}^1}{(1 - \hat{p}_i) \rho_{i,t}^0 + \hat{p}_i \rho_{i,t}^1}, \quad a \in \{0, 1\}.
\tag{13}
\]
The new set of estimates is found by maximizing (12) w.r.t. $\tilde{\theta}_t$ and $\hat{a}_{i,t}$. Since $\hat{a}_{i,t}$ and $\tilde{\theta}_t$ are statistically independent we have
\[
f(x, y, \tilde{\theta}_t) = f(x | \tilde{\theta}_t, a) \cdot f(y | \tilde{\theta}_t, a) \cdot f(a | \tilde{\theta}_t).
\tag{14}
\]
For the remaining parameters, two different ways can be followed at this point: either estimating $\{h_i\}$ at every iteration, or replacing its expression in the log-likelihood function (LLF), as shown below.

Cyclic EM – Estimating $H$: The estimates for $\tilde{x}_{t+1}$ and $\tilde{H}_{t+1}$ can be found solving
\[
\arg\min_{\tilde{x}, \tilde{H}} \|Z - \tilde{H} \|_F^2 + r^2 (y - \tilde{H} \tilde{x})^T \tilde{A}_t (y - \tilde{H} \tilde{x}) \tag{15}
\]
Although (16) resembles a TLS problem, the presence of the diagonal weighting matrix $\tilde{A}_t$ precludes a closed-form expression for the solution. Equating to zero the gradients of (16) w.r.t. $\tilde{x}$ and $\tilde{H}$, and evaluating the resulting conditions at $\tilde{x} = \tilde{x}_{t+1}$ and $\tilde{H} = \tilde{H}_{t+1}$, one respectively obtains
\[
\tilde{H}_{t+1} = \tilde{H}_{t+1} \tilde{A}_t \tilde{x}_{t+1} = \tilde{H}_{t+1} \tilde{A}_t y, 
\tag{17}
\]
\[
\tilde{H}_{t+1} + r^2 \tilde{A}_t \tilde{H}_{t+1} \tilde{x}_{t+1} \tilde{x}_{t+1} = Z + r^2 \tilde{A}_t \tilde{y} \tilde{x}_{t+1}.
\tag{18}
\]
From (17), if $\tilde{H}_{t+1}$ was available, then $\tilde{x}_{t+1}$ could be readily obtained by solving an $L \times L$ linear system. Conversely, if $\tilde{x}_{t+1}$ was available, then $\tilde{H}_{t+1}$ could also be explicitly obtained, as the following result shows:

Cyclic EM – Estimating $x$:
Lemma 1. The solution \( \hat{H}_{t+1} \) to (18) is a rank-1 perturbation of \( Z \) given by \( H_{t+1} = Z + u_{t+1} \hat{x}_{t+1}^T \), with

\[
u_{t+1} = r^2 \left( I + r^2 \left\| \hat{x}_{t+1} \right\|^2 \tilde{A}_i \right)^{-1} \tilde{A}_i (y - Z \hat{x}_{t+1}).
\]

The proof follows immediately by substituting \( H_{t+1} = Z + u_{t+1} \hat{x}_{t+1}^T \) in the left-hand side of (18). Note that \( I + r^2 \left\| \hat{x}_{t+1} \right\|^2 \tilde{A}_i \) is a diagonal matrix, and hence its inversion is computationally cheap. In order to obtain \( \hat{x}_{t+1} \) minimized w.r.t. \( \tilde{A}_i \), where \( \hat{x}_{t+1} \) is given by

\[
\hat{x}_{t+1} = \arg \min_{\hat{x}} (y - Z \hat{x})^T \tilde{A}_i (y - Z \hat{x})
\]

and then solve for \( \hat{x}_t \) in

\[
(\hat{H}^{(k)})^T \tilde{A}_i \hat{H}^{(k)} \hat{x}^{(k)} = (\hat{H}^{(k)})^T \tilde{A}_i y. \]

We then take \( \hat{x}_{t+1} = \hat{x}^{(K)} \) and \( \hat{x}_{t+1} = \hat{H}^{(K)} \). The estimate for the variance is found in terms of those of \( x \) and \( \{ \hat{x}_i \} \):

\[
\sigma_{t+1}^2 = \frac{r^2 (y^T y - \hat{\psi}_t^T \hat{x}_t) + \left\| Z - \hat{H}_{t+1} \right\|^2}{r^2 N(L + 1)}
\]

where \( \hat{\psi}_t = \hat{H}_{t+1}^T \tilde{A}_t y \). We propose to embed the CM iteration just described within the EM iterative procedure, yielding the modification of the centralized EM algorithm (CEM). In essence, at each outer EM iteration, only one inner CM iteration is performed, i.e., we take \( \hat{x}_t^{(0)} = \hat{x}_t \) and \( K = 1 \). Although the parameter trajectories of this modified version do not necessarily coincide with those of the true EM algorithm, the sets of fixed points of both schemes are the same.

Blind EM – Substituting \( H \) in the LLF: Next we propose an alternative approach in which explicit estimation of \( h_t \) is not needed. To this end, first we show how to obtain the scalar products \( \hat{h}_t^T \hat{x}_t \) featuring in (14). From Lemma 1, it follows that \( H_t = Z + u_t \hat{x}_t^T \). Therefore, after some algebra, one finds

\[
\hat{H}_t \hat{x}_t = y - (I + r^2 \left\| \hat{x}_t \right\|^2 \tilde{A}_t)^{-1} (y - Z \hat{x}_t).
\]

Using this in (14), one obtains

\[
\rho_{i,t}^a = \exp \left( -\frac{(y_i - \hat{a}_{i,k} \hat{h}_{j,k}^T \hat{x}_{t,k})^2}{2\sigma_{k,t}^2} \right), \quad a \in \{0, 1\}
\]

Now note that using again Lemma 1, the cost in (16) can be minimized w.r.t. \( H \). Substituting the optimum value of \( H \) (which depends on \( \hat{x} \)) in (16) results in the following problem after some algebraic manipulations:

\[
\hat{x}_{t+1} = \arg \min_{\hat{x}} (y - Z \hat{x})^T \hat{D}_t (\hat{x}) (y - Z \hat{x})
\]

where \( \hat{D}_t (\hat{x}) = (I + r^2 \left\| \hat{x} \right\|^2 \tilde{A}_t)^{-1} \tilde{A}_t \). Note that the cost in (25) is not quadratic due to the fact that the diagonal weighting matrix \( \hat{D}_t (\hat{x}) \) depends on \( \hat{x} \). We propose to replace \( \hat{D}_t \) by

\[
\hat{D}_t (\hat{x}) = D_t (\hat{x}_t) \approx D_t (\hat{x}) \text{ in (25) in order to obtain a quadratic problem (weighted least squares), whose solution is }
\]

\[
\hat{x}_{t+1} = (Z^T \hat{D}_t Z)^{-1} Z^T \hat{D}_t y.
\]

4. DISTRIBUTED SOLUTIONS

Assume that each node \( i = 1, \ldots, N \) only has access to its own measurement \( \{ y_i, z_i \} \) and can only communicate with a small subset of neighbors. At each node \( i \) and at time \( k \), a local copy of the parameters \( \{ \hat{x}_i, \hat{\sigma}_{i,k}^2, \tilde{h}_{i,k} \} \) (and also of \( \hat{h}_{i,k}^T \) for the CEM) is updated in terms of the information gathered from neighboring nodes. Let \( W \in \mathbb{R}^{N \times N} \) denote a weight matrix with a nonzero \( (i,j)^{th} \) entry \( W_{ij} \) only if nodes \( i \) and \( j \) can communicate with each other. We assume that the network is connected, i.e., there is a path between any pair of nodes \( \{i,j\} \). \( W \) is assumed symmetric and satisfies \( W = \frac{11}{N} \), where \( 1 \) is an all-ones vector and \( \rho(\cdot) \) denotes spectral radius. The general steps of the distributed EM estimator are summarized in Table 1, whereas the intermediate variables are specified below for each method.

**Distributed (D)-CEM**: For the D-CEM approach, the a posteriori probability \( \tilde{a}_{i,k} \) at node \( i \) and at time \( k \) in (28) is computed using

\[
\rho_{i,k}^a = \exp \left( -\frac{(y_i - \tilde{a}_{i,k} \tilde{h}_{j,k}^T \tilde{x}_{i,k})^2}{2\tilde{\sigma}_{i,k}^2} \right), \quad a \in \{0, 1\}
\]

and the intermediate variables are given by

\[
F(j,k) = a_{j,k} \tilde{h}_{j,k} \tilde{h}_{j,k}^T
\]

\[
f(j,k) = \tilde{a}_{j,k} \tilde{y}_j \tilde{h}_{j,k}
\]

\[
f_j(j,k) = r^2 (y_j - \tilde{y}_j \tilde{a}_{j,k} \tilde{h}_{j,k}^T \tilde{x}_{j,k+1}) + \| z_j - \tilde{h}_{j,k} \| ^2
\]

\( \tilde{y}_j \) denotes \( k \) (rather than \( t \) the iteration index for the distributed approaches, in order to emphasize the difference w.r.t. the centralized schemes.
For $i = 1, \ldots, N$

1. Initialize $\hat{a}_{i,0}$ and the local estimates $\hat{\theta}_{i,1}$. Initialize the intermediate variables $F(j, k), f(j, k)$ and $f_{\nu}(j, k), \forall \nu \in \{\sigma^2, a, 1\}$.

For $k \geq 1$,

2. $E$-Step: given $\hat{\theta}_{i,k}$ compute

$$\hat{a}_{i,k} = \frac{\rho^0_{i,k} \hat{p}_{i,k}}{\rho^0_{i,k} \hat{p}_{i,k} + \rho^0_{i,k}(1-\hat{p}_{i,k})} \quad (28)$$

3. $M$-Step: for every $\nu \in \{\sigma^2, a, 1\}$, compute the intermediate variables

$$\phi_{\nu}(i, k) = \sum_{j=1}^{N} W_{ij} \left[ (1-\beta_k) \phi_{\nu}(j, k-1) + \alpha_k f_{\nu}(j, k) \right] \quad (29)$$

$$\Phi(i, k) = \sum_{j=1}^{N} W_{ij} \left[ (1-\beta_k) \Phi(j, k-1) + \alpha_k F(j, k) \right] \quad (30a)$$

$$\varphi(i, k) = \sum_{j=1}^{N} W_{ij} \left[ (1-\beta_k) \varphi(j, k-1) + \alpha_k f(j, k) \right] \quad (30b)$$

where $f_1(j, k) = 1, f_0(j, k) = \hat{a}_{i,k}, \forall j, k$ and

$$\alpha_k = \frac{1}{\beta_k}, \beta_k = \frac{1}{\beta_k^2}, 0 < \delta < 1, \ k = 1, 2, \ldots \ (31)$$

Solve for $\hat{x}_{i,k+1}$ in the $L \times L$ linear system

$$\Phi(i, k) \hat{x}_{i,k+1} = \varphi(i, k) \quad (32)$$

and update

$$\hat{\sigma}^2_{i,k+1} = \frac{1}{r^2(L+1)} \frac{\varphi_{i,k}(i, k)}{\varphi_{i,k}(k, k)}, \ \hat{p}_{i,k+1} = \frac{\phi_{i,k}(i, k)}{\phi_{i,k}(k, k)}. \quad (33)$$

4. Repeat steps 2 and 3 until convergence.

### Table 1. Diffusion-Based Distributed EM Algorithm

**Distributed (D)-BEM:** For the D-BEM approach, the a posteriori probabilities in (28) are computed as

$$\rho_{i,k}^0 = \exp \left( -\frac{1}{2 \hat{\sigma}^2_{i,k}} \left( \frac{y_i - a z_i^T \hat{x}_{i,k}}{1 + a r^2 \| \hat{x}_{i,k} \|^2 \hat{a}_{i,k}} \right)^2 \right), \ a \in \{0, 1\} \quad (37)$$

whereas the intermediate variables are given by

$$F(j, k) = \hat{d}_{j,k} z_j z_j^T \quad (38)$$

$$f(j, k) = \hat{d}_{j,k} y_j z_j \quad (39)$$

$$f_{\nu}(j, k) = \hat{r}^2 (\hat{d}_{j,k} (y_j - z_j^T \hat{x}_{j,k} + 1)^2 + (1 - \hat{d}_{j,k}) y_j^2) \quad (40)$$

with $\hat{d}_{j,k} = \hat{a}_{j,k}/(1 + r^2 \| \hat{x}_{j,k} \|^2 \hat{a}_{j,k})$.  

### 5. NUMERICAL RESULTS

Computer simulations of the proposed EM-based estimators have been performed in a network composed of $N = 100$ nodes randomly deployed on a unit square with an average connectivity radius $r_c = 0.25$. We set $L = 5, p = 0.8$ and $r = 1$, and generate the entries of $H$ as zero-mean i.i.d. Gaussian random variables of unit variance. The distributed schemes are run with a Metropolis weight matrix $W$ [14] and $\delta = 0.8$. The local estimates are initialized as follows: $\hat{a}_{i,0} = \hat{p}_{i,1} = 1/2, \ x_{i,1} = y_i z_i / z_i^T z_i$ and $\hat{\sigma}^2_{i,1} = y_i^2 (1 - \hat{a}_{i,0})$. Conditioned on $H$, the signal-to-noise (SNR) is given by

$$\text{SNR} = \frac{x^T H^T H x + tr(H^T H)}{N(L+1)\sigma^2} \leq \frac{(1 + \| x \|^2) \| H \|^2_F}{N(L+1)\sigma^2}. \quad (41)$$

For the simulations, we take the upper bound in (41) as the SNR, as it only depends on $\| x \|^2$ and $\| H \|^2_F$. The performance metric considered is the normalized MSE, defined as

$$\text{NMSE} \{ \hat{x}(k) \} = \frac{1}{N \| x \|^2} \sum_{i=1}^{N} \mathbb{E} \left[ \| \hat{x}_i(k) - x_i \|^2 \right]. \quad (42)$$

Fig. 1 depicts the NMSE vs. SNR in dB for the proposed EM-based estimators, the TLS, the OLS, and their respective clairvoyant versions CV-TLS and CV-OLS.
